1. Overview

Pig provides extensive support for user-defined functions (UDFs) as a way to specify custom processing. Functions can be a part of almost every operator in Pig. This document describes how to use existing functions as well as how to write your own functions (see also [Pig Properties](#).)

2. Eval Functions

2.1. How to Use a Simple Eval Function

Eval is the most common type of function. It can be used in FOREACH statements as shown in this script:

```
-- myscript.pig
REGISTER myudfs.jar;
A = LOAD 'student_data' AS (name: chararray, age: int, gpa: float);
B = FOREACH A GENERATE myudfs.UPPER(name);
DUMP B;
```

The command below can be used to run the script. Note that all examples in this document run in local mode for simplicity but the examples can also run in Hadoop mode. For more information on how to run Pig, please see the PigTutorial.

```
java -cp pig.jar org.apache.pig.Main -x local myscript.pig
```

The first line of the script provides the location of the `jar` file that contains the UDF. (Note that there are no quotes around the jar file. Having quotes would result in a syntax error.) To locate the jar file, Pig first checks the `classpath`. If the jar file can't be found in the classpath, Pig assumes that the location is either an absolute path or a path relative to the location from which Pig was invoked. If the jar file can't be found, an error will be printed: `java.io.IOException: Can't read jar file: myudfs.jar`.

Multiple `register` commands can be used in the same script. If the same fully-qualified function is present in multiple jars, the first occurrence will be used consistently with Java semantics.

The name of the UDF has to be fully qualified with the package name or an error will be reported: `java.io.IOException: Cannot instantiate:UPPER`. Also, the function name is case sensitive (UPPER and upper are not the same). A UDF can take one or more parameters. The exact signature of the function should clear from its documentation.

The function provided in this example takes an ASCII string and produces its uppercase

version. If you are familiar with column transformation functions in SQL, you will recognize that UPPER fits this concept. However, as we will see later in the document, eval functions in Pig go beyond column transformation functions and include aggregate and filter functions.

If you are just a user of UDFs, this is most of what you need to know about UDFs to use them in your code.

2.2. How to Write a Simple Eval Function

Let's now look at the implementation of the UPPER UDF.

```
package myudfs;
import java.io.IOException;
import org.apache.pig.EvalFunc;
import org.apache.pig.data.Tuple;
import org.apache.pig.impl.util.WrappedIOException;

public class UPPER extends EvalFunc<String>
{
    public String exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        try{
            String str = (String)input.get(0);
            return str.toUpperCase();
        }catch(Exception e){
            throw WrappedIOException.wrap("Caught exception processing
input row ", e);
        }
    }
}
```

The first line indicates that the function is part of the `myudfs` package. The UDF class extends the `EvalFunc` class which is the base class for all eval functions. It is parameterized with the return type of the UDF which is a Java `String` in this case. We will look into the `EvalFunc` class in more detail later, but for now all we need to do is to implement the `exec` function. This function is invoked on every input tuple. The input into the function is a tuple with input parameters in the order they are passed to the function in the Pig script. In our example, it will contain a single string field corresponding to the student name.

The first thing to decide is what to do with invalid data. This depends on the format of the data. If the data is of type `bytearray` it means that it has not yet been converted to its proper type. In this case, if the format of the data does not match the expected type, a `NULL` value should be returned. If, on the other hand, the input data is of another type, this means that the conversion has already happened and the data should be in the correct format. This is the case with our example and that's why it throws an error (line 16.) Note that

`WrappedIOException` is a helper class to convert the actual exception to an `IOException`.

Also, note that lines 10-11 check if the input data is null or empty and if so returns null.

The actual function implementation is on lines 13-14 and is self-explanatory.

Now that we have the function implemented, it needs to be compiled and included in a jar. You will need to build `pig.jar` to compile your UDF. You can use the following set of commands to checkout the code from SVN repository and create `pig.jar`:

```
svn co http://svn.apache.org/repos/asf/pig/trunk
cd trunk
ant
```

You should see `pig.jar` in your current working directory. The set of commands below first compiles the function and then creates a jar file that contains it.

```
cd myudfs
javac -cp pig.jar UPPER.java
cd ..
jar -cf myudfs.jar myudfs
```

You should now see `myudfs.jar` in your current working directory. You can use this jar with the script described in the previous section.

2.3. Aggregate Functions

Aggregate functions are another common type of eval function. Aggregate functions are usually applied to grouped data, as shown in this script:

```
-- myscript2.pig
A = LOAD 'student_data' AS (name: chararray, age: int, gpa: float);
B = GROUP A BY name;
C = FOREACH B GENERATE group, COUNT(A);
DUMP C;
```

The script above uses the `COUNT` function to count the number of students with the same name. There are a couple of things to note about this script. First, even though we are using a function, there is no `register` command. Second, the function is not qualified with the package name. The reason for both is that `COUNT` is a builtin function meaning that it comes with the Pig distribution. These are the only two differences between builtins and UDFs. Builtins are discussed in more detail later in this document.

An aggregate function is an eval function that takes a bag and returns a scalar value. One interesting and useful property of many aggregate functions is that they can be computed incrementally in a distributed fashion. We call these functions algebraic. `COUNT` is an

example of an algebraic function because we can count the number of elements in a subset of the data and then sum the counts to produce a final output. In the Hadoop world, this means that the partial computations can be done by the map and combiner, and the final result can be computed by the reducer.

It is very important for performance to make sure that aggregate functions that are algebraic are implemented as such. Let's look at the implementation of the COUNT function to see what this means. (Error handling and some other code is omitted to save space. The full code can be accessed [here](#).)

```
public class COUNT extends EvalFunc<Long> implements Algebraic{
    public Long exec(Tuple input) throws IOException {return count(input);}
    public String getInitial() {return Initial.class.getName();}
    public String getIntermed() {return Intermed.class.getName();}
    public String getFinal() {return Final.class.getName();}
    static public class Initial extends EvalFunc<Tuple> {
        public Tuple exec(Tuple input) throws IOException {return
TupleFactory.getInstance().newTuple(count(input));}
    }
    static public class Intermed extends EvalFunc<Tuple> {
        public Tuple exec(Tuple input) throws IOException {return
TupleFactory.getInstance().newTuple(sum(input));}
    }
    static public class Final extends EvalFunc<Long> {
        public Tuple exec(Tuple input) throws IOException {return
sum(input);}
    }
    static protected Long count(Tuple input) throws ExecException {
        Object values = input.get(0);
        if (values instanceof DataBag) return ((DataBag)values).size();
        else if (values instanceof Map) return new
Long(((Map)values).size());
    }
    static protected Long sum(Tuple input) throws ExecException,
NumberFormatException {
        DataBag values = (DataBag)input.get(0);
        long sum = 0;
        for (Iterator (Tuple) it = values.iterator(); it.hasNext();) {
            Tuple t = it.next();
            sum += (Long)t.get(0);
        }
        return sum;
    }
}
```

COUNT implements Algebraic interface which looks like this:

```
public interface Algebraic{
    public String getInitial();
    public String getIntermed();
    public String getFinal();
}
```

```
}
```

For a function to be algebraic, it needs to implement `Algebraic` interface that consist of definition of three classes derived from `EvalFunc`. The contract is that the `exec` function of the `Initial` class is called once and is passed the original input tuple. Its output is a tuple that contains partial results. The `exec` function of the `Intermed` class can be called zero or more times and takes as its input a tuple that contains partial results produced by the `Initial` class or by prior invocations of the `Intermed` class and produces a tuple with another partial result. Finally, the `exec` function of the `Final` class is called and produces the final result as a scalar type.

Here's the way to think about this in the Hadoop world. The `exec` function of the `Initial` class is invoked once by the map process and produces partial results. The `exec` function of the `Intermed` class is invoked once by each combiner invocation (which can happen zero or more times) and also produces partial results. The `exec` function of the `Final` class is invoked once by the reducer and produces the final result.

Take a look at the `COUNT` implementation to see how this is done. Note that the `exec` function of the `Initial` and `Intermed` classes is parameterized with `Tuple` and the `exec` of the `Final` class is parameterized with the real type of the function, which in the case of the `COUNT` is `Long`. Also, note that the fully-qualified name of the class needs to be returned from `getInitial`, `getIntermed`, and `getFinal` methods.

2.4. Filter Functions

Filter functions are eval functions that return a boolean value. Filter functions can be used anywhere a Boolean expression is appropriate, including the `FILTER` operator or `bincond` expression.

The example below uses the `IsEmpty` builtin filter function to implement joins.

```
-- inner join
A = LOAD 'student_data' AS (name: chararray, age: int, gpa: float);
B = LOAD 'voter_data' AS (name: chararray, age: int, registration:
chararray, contributions: float);
C = COGROUP A BY name, B BY name;
D = FILTER C BY not IsEmpty(A);
E = FILTER D BY not IsEmpty(B);
F = FOREACH E GENERATE flatten(A), flatten(B);
DUMP F;
```

Note that, even if filtering is omitted, the same results will be produced because the `foreach` results is a cross product and cross products get rid of empty bags. However, doing up-front filtering is more efficient since it reduces the input of the cross product.

```
-- full outer join
```

```

A = LOAD 'student_data' AS (name: chararray, age: int, gpa: float);
B = LOAD 'voter_data' AS (name: chararray, age: int, registration:
chararray, contributions: float);
C = COGROUP A BY name, B BY name;
D = FOREACH C GENERATE group, flatten((IsEmpty(A) ? null : A)),
flatten((IsEmpty(B) ? null : B));
dump D

```

The implementation of the `IsEmpty` function looks like this:

```

import java.io.IOException;
import java.util.Map;
import org.apache.pig.FilterFunc;
import org.apache.pig.backend.executionengine.ExecException;
import org.apache.pig.data.DataBag;
import org.apache.pig.data.Tuple;
import org.apache.pig.data.DataType;
import org.apache.pig.impl.util.WrappedIOException;

public class IsEmpty extends FilterFunc {
    public Boolean exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        try {
            Object values = input.get(0);
            if (values instanceof DataBag)
                return ((DataBag)values).size() == 0;
            else if (values instanceof Map)
                return ((Map)values).size() == 0;
            else{
                throw new IOException("Cannot test a " +
                    DataType.findTypeName(values) + " for emptiness.");
            }
        } catch (ExecException ee) {
            throw WrappedIOException.wrap("Caught exception processing
input row ", ee);
        }
    }
}

```

2.5. Pig Types

The main thing to know about Pig's type system is that Pig uses native Java types for almost all of its types, as shown in this table.

Pig Type	Java Class
bytearray	DataByteArray
chararray	String

int	Integer
long	Long
float	Float
double	Double
tuple	Tuple
bag	DataBag
map	Map<Object, Object>

All Pig-specific classes are available [here](#).

Tuple and DataBag are different in that they are not concrete classes but rather interfaces. This enables users to extend Pig with their own versions of tuples and bags. As a result, UDFs cannot directly instantiate bags or tuples; they need to go through factory classes: TupleFactory and BagFactory.

The builtin TOKENIZE function shows how bags and tuples are created. A function takes a text string as input and returns a bag of words from the text. (Note that currently Pig bags always contain tuples.)

```
package org.apache.pig.builtin;

import java.io.IOException;
import java.util.StringTokenizer;
import org.apache.pig.EvalFunc;
import org.apache.pig.data.BagFactory;
import org.apache.pig.data.DataBag;
import org.apache.pig.data.Tuple;
import org.apache.pig.data.TupleFactory;

public class TOKENIZE extends EvalFunc<DataBag> {
    TupleFactory mTupleFactory = TupleFactory.getInstance();
    BagFactory mBagFactory = BagFactory.getInstance();

    public DataBag exec(Tuple input) throws IOException {
        try {
            DataBag output = mBagFactory.newDefaultBag();
            Object o = input.get(0);
            if (!(o instanceof String)) {
                throw new IOException("Expected input to be chararray, but
```

```

got " + o.getClass().getName());
    }
    StringTokenizer tok = new StringTokenizer((String)o, " \",()*\"",
false);
    while (tok.hasMoreTokens())
output.add(mTupleFactory.newTuple(tok.nextToken()));
    return output;
    } catch (ExecException ee) {
        // error handling goes here
    }
}
}

```

2.6. Schema

The latest version of Pig uses type information for validation and performance. It is important for UDFs to participate in type propagation. Until now, our UDFs made no effort to communicate their output schema to Pig. This is because, most of the time, Pig can figure out this information by using Java's [Reflection](#). If your UDF returns a scalar or a map, no work is required. However, if your UDF returns a tuple or a bag (of tuples), it needs to help Pig figure out the structure of the tuple.

If a UDF returns a tuple or a bag and schema information is not provided, Pig assumes that the tuple contains a single field of type `bytearray`. If this is not the case, then not specifying the schema can cause failures. We look at this next.

Let's assume that we have UDF Swap that, given a tuple with two fields, swaps their order. Let's assume that the UDF does not specify a schema and look at the scripts below:

```

register myudfs.jar;
A = load 'student_data' as (name: chararray, age: int, gpa: float);
B = foreach A generate flatten(myudfs.Swap(name, age)), gpa;
C = foreach B generate $2;
D = limit B 20;
dump D;

```

This script will result in the following error cause by line 4.

```

java.io.IOException: Out of bound access. Trying to access non-existent
column: 2. Schema {bytearray,gpa: float} has 2 column(s).

```

This is because Pig is only aware of two columns in B while line 4 is requesting the third column of the tuple. (Column indexing in Pig starts with 0.)

The function, including the schema, looks like this:

```

package myudfs;
import java.io.IOException;
import org.apache.pig.EvalFunc;

```

```

import org.apache.pig.data.Tuple;
import org.apache.pig.data.TupleFactory;
import org.apache.pig.impl.logicalLayer.schema.Schema;
import org.apache.pig.data.DataType;

public class Swap extends EvalFunc<Tuple> {
    public Tuple exec(Tuple input) throws IOException {
        if (input == null || input.size() < 2)
            return null;
        try{
            Tuple output = TupleFactory.getInstance().newTuple(2);
            output.set(0, input.get(1));
            output.set(1, input.get(0));
            return output;
        } catch (Exception e){
            System.err.println("Failed to process input; error - " +
e.getMessage());
            return null;
        }
    }
    public Schema outputSchema(Schema input) {
        try{
            Schema tupleSchema = new Schema();
            tupleSchema.add(input.getField(1));
            tupleSchema.add(input.getField(0));
            return new Schema(new
Schema.FieldSchema(getSchemaName(this.getClass().getName().toLowerCase(),
input),tupleSchema, DataType.TUPLE));
        }catch (Exception e){
            return null;
        }
    }
}

```

The function creates a schema with a single field (of type `FieldSchema`) of type `tuple`. The name of the field is constructed using the `getSchemaName` function of the `EvalFunc` class. The name consists of the name of the UDF function, the first parameter passed to it, and a sequence number to guarantee uniqueness. In the previous script, if you replace `dump D;` with `describe B;`, you will see the following output:

```

B: {myudfs.swap_age_3::age: int,myudfs.swap_age_3::name: chararray,gpa:
float}

```

The second parameter to the `FieldSchema` constructor is the schema representing this field, which in this case is a tuple with two fields. The third parameter represents the type of the schema, which in this case is a `TUPLE`. All supported schema types are defined in the `org.apache.pig.data.DataType` class.

```

public class DataType {
    public static final byte UNKNOWN = 0;
}

```

```

    public static final byte NULL      = 1;
    public static final byte BOOLEAN  = 5; // internal use only
    public static final byte BYTE     = 6; // internal use only
    public static final byte INTEGER  = 10;
    public static final byte LONG     = 15;
    public static final byte FLOAT    = 20;
    public static final byte DOUBLE   = 25;
    public static final byte BYTEARRAY = 50;
    public static final byte CHARARRAY = 55;
    public static final byte MAP      = 100;
    public static final byte TUPLE    = 110;
    public static final byte BAG      = 120;
    public static final byte ERROR    = -1;
    // more code here
}

```

You need to import the `org.apache.pig.data.DataType` class into your code to define schemas. You also need to import the schema class `org.apache.pig.impl.logicalLayer.schema.Schema`.

The example above shows how to create an output schema for a tuple. Doing this for a bag is very similar. Let's extend the `TOKENIZE` function to do that:

```

package org.apache.pig.builtin;

import java.io.IOException;
import java.util.StringTokenizer;
import org.apache.pig.EvalFunc;
import org.apache.pig.data.BagFactory;
import org.apache.pig.data.DataBag;
import org.apache.pig.data.Tuple;
import org.apache.pig.data.TupleFactory;
import org.apache.pig.impl.logicalLayer.schema.Schema;
import org.apache.pig.data.DataType;

public class TOKENIZE extends EvalFunc<DataBag> {
    TupleFactory mTupleFactory = TupleFactory.getInstance();
    BagFactory mBagFactory = BagFactory.getInstance();
    public DataBag exec(Tuple input) throws IOException {
        try {
            DataBag output = mBagFactory.newDefaultBag();
            Object o = input.get(0);
            if (!(o instanceof String)) {
                throw new IOException("Expected input to be chararray, but got " + o.getClass().getName());
            }
            StringTokenizer tok = new StringTokenizer((String)o, " \",()*\"", false);
            while (tok.hasMoreTokens())
                output.add(mTupleFactory.newTuple(tok.nextToken()));
            return output;
        } catch (ExecException ee) {
            // error handling goes here
        }
    }
}

```

```

    }
}
public Schema outputSchema(Schema input) {
    try{
        Schema bagSchema = new Schema();
        bagSchema.add(new Schema.FieldSchema("token",
DataType.CHARARRAY));

        return new Schema(new
Schema.FieldSchema(getSchemaName(this.getClass().getName().toLowerCase(),
input),
                                bagSchema,
DataType.BAG));
    }catch (Exception e){
        return null;
    }
}
}

```

As you can see, this is very similar to the output schema definition in the `Swap` function. One difference is that instead of reusing input schema, we create a brand new field schema to represent the tokens stored in the bag. The other difference is that the type of the schema created is `BAG` (not `TUPLE`).

2.7. Error Handling

There are several types of errors that can occur in a UDF:

1. An error that affects a particular row but is not likely to impact other rows. An example of such an error would be a malformed input value or divide by zero problem. A reasonable handling of this situation would be to emit a warning and return a null value. `ABS` function in the next section demonstrates this approach. The current approach is to write the warning to `stderr`. Eventually we would like to pass a logger to the UDFs. Note that returning a `NULL` value only makes sense if the malformed value is of type `bytearray`. Otherwise the proper type has been already created and should have an appropriate value. If this is not the case, it is an internal error and should cause the system to fail. Both cases can be seen in the implementation of the `ABS` function in the next section.
2. An error that affects the entire processing but can succeed on retry. An example of such a failure is the inability to open a lookup file because the file could not be found. This could be a temporary environmental issue that can go away on retry. A UDF can signal this to Pig by throwing an `IOException` as with the case of the `ABS` function below.
3. An error that affects the entire processing and is not likely to succeed on retry. An example of such a failure is the inability to open a lookup file because of file permission problems. Pig currently does not have a way to handle this case. Hadoop does not have a way to handle this case either. It will be handled the same way as 2 above.

Pig provides a helper class `WrappedIOException`. The intent here is to allow you to convert any exception into `IOException`. Its usage can be seen in the `UPPER` function in our first example.

2.8. Function Overloading

Before the type system was available in Pig, all values for the purpose of arithmetic calculations were assumed to be doubles as the safest choice. However, this is not very efficient if the data is actually of type integer or long. (We saw about a 2x slowdown of a query when using double where integer could be used.) Now that Pig supports types we can take advantage of the type information and choose the function that is most efficient for the provided operands.

UDF writers are encouraged to provide type-specific versions of a function if this can result in better performance. On the other hand, we don't want the users of the functions to worry about different functions - the right thing should just happen. Pig allows for this via a function table mechanism as shown in the next example.

This example shows the implementation of the `ABS` function that returns the absolute value of a numeric value passed to it as input.

```
import java.io.IOException;
import java.util.List;
import java.util.ArrayList;
import org.apache.pig.EvalFunc;
import org.apache.pig.FuncSpec;
import org.apache.pig.data.Tuple;
import org.apache.pig.impl.logicalLayer.FrontendException;
import org.apache.pig.impl.util.WrappedIOException;
import org.apache.pig.impl.logicalLayer.schema.Schema;
import org.apache.pig.data.DataType;

public class ABS extends EvalFunc<Double> {
    public Double exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        Double d;
        try{
            d = DataType.toDouble(input.get(0));
        } catch (NumberFormatException nfe){
            System.err.println("Failed to process input; error - " +
nfe.getMessage());
            return null;
        } catch (Exception e){
            throw WrappedIOException.wrap("Caught exception processing
input row ", e);
        }
        return Math.abs(d);
    }
}
```

```

    }
    public List (FuncSpec) getArgToFuncMapping() throws FrontendException {
        List (FuncSpec) funcList = new ArrayList (FuncSpec) ();
        funcList.add(new FuncSpec(this.getClass().getName(), new Schema(new
Schema.FieldSchema(null, DataType.BYTEARRAY))));
        funcList.add(new FuncSpec(DoubleAbs.class.getName(), new
Schema(new Schema.FieldSchema(null, DataType.DOUBLE))));
        funcList.add(new FuncSpec(FloatAbs.class.getName(), new
Schema(new Schema.FieldSchema(null, DataType.FLOAT))));
        funcList.add(new FuncSpec(IntAbs.class.getName(), new Schema(new
Schema.FieldSchema(null, DataType.INTEGER))));
        funcList.add(new FuncSpec(LongAbs.class.getName(), new Schema(new
Schema.FieldSchema(null, DataType.LONG))));
        return funcList;
    }
}

```

The main thing to notice in this example is the `getArgToFuncMapping()` method. This method returns a list that contains a mapping from the input schema to the class that should be used to handle it. In this example the main class handles the `bytearray` input and outsources the rest of the work to other classes implemented in separate files in the same package. The example of one such class is below. This class handles integer input values.

```

import java.io.IOException;
import org.apache.pig.impl.util.WrappedIOException;
import org.apache.pig.EvalFunc;
import org.apache.pig.data.Tuple;

public class IntAbs extends EvalFunc<Integer> {
    public Integer exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        Integer d;
        try{
            d = (Integer)input.get(0);
        } catch (Exception e){
            throw WrappedIOException.wrap("Caught exception processing
input row ", e);
        }
        return Math.abs(d);
    }
}

```

A note on error handling. The `ABS` class covers the case of the `bytearray` which means the data has not been converted yet to its actual type. This is why a null value is returned when `NumberFormatException` is encountered. However, the `IntAbs` function is only called if the data is already of type `Integer` which means it has already been converted to the real type and bad format has been dealt with. This is why an exception is thrown if the input can't be cast to `Integer`.

The example above covers a reasonably simple case where the UDF only takes one

parameter and there is a separate function for each parameter type. However, this will not always be the case. If Pig can't find an exact match it tries to do a best match. The rule for the best match is to find the most efficient function that can be used safely. This means that Pig must find the function that, for each input parameter, provides the smallest type that is equal to or greater than the input type. The type progression rules are:
`int=>=long=>=float=>=double`.

For instance, let's consider function MAX which is part of the piggybank described later in this document. Given two values, the function returns the larger value. The function table for MAX looks like this:

```
public List (FuncSpec) getArgToFuncMapping() throws FrontendException {
    List (FuncSpec) funcList = new ArrayList (FuncSpec) ();
    Util.addToFunctionList(funcList, IntMax.class.getName(),
        DataType.INTEGER);
    Util.addToFunctionList(funcList, DoubleMax.class.getName(),
        DataType.DOUBLE);
    Util.addToFunctionList(funcList, FloatMax.class.getName(),
        DataType.FLOAT);
    Util.addToFunctionList(funcList, LongMax.class.getName(),
        DataType.LONG);

    return funcList;
}
```

The `Util.addToFunctionList` function is a helper function that adds an entry to the list as the first argument, with the key of the class name passed as the second argument, and the schema containing two fields of the same type as the third argument.

Let's now see how this function can be used in a Pig script:

```
REGISTER piggybank.jar
A = LOAD 'student_data' AS (name: chararray, gpa1: float, gpa2: double);
B = FOREACH A GENERATE name,
    org.apache.pig.piggybank.evaluation.math.MAX(gpa1, gpa2);
DUMP B;
```

In this example, the function gets one parameter of type `float` and another of type `double`. The best fit will be the function that takes two double values. Pig makes this choice on the user's behalf by inserting implicit casts for the parameters. Running the script above is equivalent to running the script below:

```
A = LOAD 'student_data' AS (name: chararray, gpa1: float, gpa2: double);
B = FOREACH A GENERATE name,
    org.apache.pig.piggybank.evaluation.math.MAX((double)gpa1, gpa2);
DUMP B;
```

A special case of the best fit approach is handling data without a schema specified. The

type for this data is interpreted as `bytearray`. Since the type of the data is not known, there is no way to choose a best fit version. The only time a cast is performed is when the function table contains only a single entry. This works well to maintain backward compatibility.

Let's revisit the `UPPER` function from our first example. As it is written now, it would only work if the data passed to it is of type `chararray`. To make it work with data whose type is not explicitly set, a function table with a single entry needs to be added:

```
package myudfs;
import java.io.IOException;
import org.apache.pig.EvalFunc;
import org.apache.pig.data.Tuple;

public class UPPER extends EvalFunc<String>
{
    public String exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        try{
            String str = (String)input.get(0);
            return str.toUpperCase();
        }catch(Exception e){
            System.err.println("WARN: UPPER: failed to process input; error
- " + e.getMessage());
            return null;
        }
    }
    public List (FuncSpec) getArgToFuncMapping() throws FrontendException {
        List (FuncSpec) funcList = new ArrayList (FuncSpec) ();
        funcList.add(new FuncSpec(this.getClass().getName(), new Schema(new
Schema.FieldSchema(null, DataType.CHARARRAY)));
        return funcList;
    }
}
```

Now the following script will run:

```
-- this is myscript.pig
REGISTER myudfs.jar;
A = LOAD 'student_data' AS (name, age, gpa);
B = FOREACH A GENERATE myudfs.UPPER(name);
DUMP B;
```

2.9. Reporting Progress

A challenge of running a large shared system is to make sure system resources are used efficiently. One aspect of this challenge is detecting runaway processes that are no longer making progress. Pig uses a heartbeat mechanism for this purpose. If any of the tasks stops sending a heartbeat, the system assumes that it is dead and kills it.

Most of the time, single-tuple processing within a UDF is very short and does not require a UDF to heartbeat. The same is true for aggregate functions that operate on large bags because bag iteration code takes care of it. However, if you have a function that performs a complex computation that can take an order of minutes to execute, you should add a progress indicator to your code. This is very easy to accomplish. The `EvalFunc` function provides a progress function that you need to call in your `exec` method.

For instance, the `UPPER` function would now look as follows:

```
public class UPPER extends EvalFunc<String>
{
    public String exec(Tuple input) throws IOException {
        if (input == null || input.size() == 0)
            return null;
        try{
            reporter.progress();
            String str = (String)input.get(0);
            return str.toUpperCase();
        }catch(Exception e){
            throw WrappedIOException.wrap("Caught exception
processing input row ", e);
        }
    }
}
```

2.10. Import Lists

An import list allows you to specify the package to which a UDF or a group of UDFs belong, eliminating the need to qualify the UDF on every call. An import list can be specified via the `udf.import.list` Java property on the Pig command line:

```
pig -Dudf.import.list=com.yahoo.yst.sds.ULT
```

You can supply multiple locations as well:

```
pig
-Dudf.import.list=com.yahoo.yst.sds.ULT:org.apache.pig.piggybank.evaluation
```

To make use of import scripts, do the following:

```
myscript.pig:
A = load '/data/SDS/data/searcg_US/20090820' using ULTLoader as (s, m, l);
....

command:
pig -cp sds.jar -Dudf.import.list=com.yahoo.yst.sds.ULT myscript.pig
```

3. Load/Store Functions

The load/store user-defined functions control how data goes into Pig and comes out of Pig. Often, the same function handles both input and output but that does not have to be the case.

With Pig 0.7.0, the Pig load/store API moves closer to using Hadoop's InputFormat and OutputFormat classes. This enables Pig users/developers to create new LoadFunc and StoreFunc implementation based on existing Hadoop InputFormat and OutputFormat classes with minimal code. The complexity of reading the data and creating a record will now lie in the InputFormat and likewise on the writing end, the complexity of writing will lie in the OutputFormat. This enables Pig to easily read/write data in new storage formats as and when an Hadoop InputFormat and OutputFormat is available for them.

Note: Both the LoadFunc and StoreFunc implementations should use the Hadoop 20 API based classes (InputFormat/OutputFormat and related classes) under the **new** org.apache.hadoop.mapreduce package instead of the old org.apache.hadoop.mapred package.

3.1. Load Functions

[LoadFunc](#) abstract class has the main methods for loading data and for most use cases it would suffice to extend it. There are three other optional interfaces which can be implemented to achieve extended functionality:

- [LoadMetadata](#) has methods to deal with metadata - most implementation of loaders don't need to implement this unless they interact with some metadata system. The getSchema() method in this interface provides a way for loader implementations to communicate the schema of the data back to pig. If a loader implementation returns data comprised of fields of real types (rather than DataByteArray fields), it should provide the schema describing the data returned through the getSchema() method. The other methods are concerned with other types of metadata like partition keys and statistics. Implementations can return null return values for these methods if they are not applicable for that implementation.
- [LoadPushDown](#) has methods to push operations from Pig runtime into loader implementations. Currently only the pushProjection() method is called by Pig to communicate to the loader the exact fields that are required in the Pig script. The loader implementation can choose to honor the request (return only those fields required by Pig script) or not honor the request (return all fields in the data). If the loader implementation can efficiently honor the request, it should implement LoadPushDown to improve query performance. (Irrespective of whether the implementation can or cannot honor the request, if the implementation also implements getSchema(), the schema returned in getSchema() should describe the entire tuple of data.)
 - pushProjection(): This method tells LoadFunc which fields are required in the Pig script, thus enabling LoadFunc to optimize performance by loading only those fields

that are needed. `pushProjection()` takes a `RequiredFieldList`. `RequiredFieldList` includes a list of `RequiredField`: each `RequiredField` indicates a field required by the Pig script; each `RequiredField` includes index, alias, type (which is reserved for future use), and subFields. Pig will use the column index `RequiredField.index` to communicate with the `LoadFunc` about the fields required by the Pig script. If the required field is a map, Pig will optionally pass `RequiredField.subFields` which contains a list of keys that the Pig script needs for the map. For example, if the Pig script needs two keys for the map, "key1" and "key2", the subFields for that map will contain two `RequiredField`; the alias field for the first `RequiredField` will be "key1" and the alias for the second `RequiredField` will be "key2". `LoadFunc` will use `RequiredFieldResponse.requiredFieldRequestHonored` to indicate whether the `pushProjection()` request is honored.

- [LoadCaster](#) has methods to convert byte arrays to specific types. A loader implementation should implement this if casts (implicit or explicit) from `DataByteArray` fields to other types need to be supported.

The `LoadFunc` abstract class is the main class to extend for implementing a loader. The methods which need to be overridden are explained below:

- `getInputFormat()`: This method is called by Pig to get the `InputFormat` used by the loader. The methods in the `InputFormat` (and underlying `RecordReader`) are called by Pig in the same manner (and in the same context) as by Hadoop in a MapReduce java program. If the `InputFormat` is a Hadoop packaged one, the implementation should use the new API based one under `org.apache.hadoop.mapreduce`. If it is a custom `InputFormat`, it should be implemented using the new API in `org.apache.hadoop.mapreduce`. If a custom loader using a text-based `InputFormat` or a file-based `InputFormat` would like to read files in all subdirectories under a given input directory recursively, then it should use the `PigTextInputFormat` and `PigFileInputFormat` classes provided in `org.apache.pig.backend.hadoop.executionengine.mapReduceLayer`. The Pig `InputFormat` classes work around a current limitation in the Hadoop `TextInputFormat` and `FileInputFormat` classes which only read one level down from the provided input directory. For example, if the input in the load statement is 'dir1' and there are subdirs 'dir2' and 'dir2/dir3' beneath dir1, the Hadoop `TextInputFormat` and `FileInputFormat` classes read the files under 'dir1' only. Using `PigTextInputFormat` or `PigFileInputFormat` (or by extending them), the files in all the directories can be read.
- `setLocation()`: This method is called by Pig to communicate the load location to the loader. The loader should use this method to communicate the same information to the underlying `InputFormat`. This method is called multiple times by pig - implementations should bear this in mind and should ensure there are no inconsistent side effects due to the multiple calls.
- `prepareToRead()`: Through this method the `RecordReader` associated with the

InputFormat provided by the LoadFunc is passed to the LoadFunc. The RecordReader can then be used by the implementation in getNext() to return a tuple representing a record of data back to pig.

- getNext(): The meaning of getNext() has not changed and is called by Pig runtime to get the next tuple in the data - in this method the implementation should use the underlying RecordReader and construct the tuple to return.

The following methods have default implementations in LoadFunc and should be overridden only if needed:

- setUdfContextSignature(): This method will be called by Pig both in the front end and back end to pass a unique signature to the Loader. The signature can be used to store into the UDFContext any information which the Loader needs to store between various method invocations in the front end and back end. A use case is to store RequiredFieldList passed to it in LoadPushDown.pushProjection(RequiredFieldList) for use in the back end before returning tuples in getNext(). The default implementation in LoadFunc has an empty body. This method will be called before other methods.
- relativeToAbsolutePath(): Pig runtime will call this method to allow the Loader to convert a relative load location to an absolute location. The default implementation provided in LoadFunc handles this for FileSystem locations. If the load source is something else, loader implementation may choose to override this.

Example Implementation

The loader implementation in the example is a loader for text data with line delimiter as '\n' and '\t' as default field delimiter (which can be overridden by passing a different field delimiter in the constructor) - this is similar to current PigStorage loader in Pig. The implementation uses an existing Hadoop supported Inputformat - TextInputFormat - as the underlying InputFormat.

```
public class SimpleTextLoader extends LoadFunc {
    protected RecordReader in = null;
    private byte fieldDel = '\t';
    private ArrayList<Object> mProtoTuple = null;
    private TupleFactory mTupleFactory = TupleFactory.getInstance();
    private static final int BUFFER_SIZE = 1024;

    public SimpleTextLoader() {
    }

    /**
     * Constructs a Pig loader that uses specified character as a field
     * delimiter.
     *
     * @param delimiter
     *         the single byte character that is used to separate
```

```

fields.
    *          ("\t" is the default.)
    */
    public SimpleTextLoader(String delimiter) {
        this();
        if (delimiter.length() == 1) {
            this.fieldDel = (byte)delimiter.charAt(0);
        } else if (delimiter.length() > 1 && delimiter.charAt(0) == '\\')
        {
            switch (delimiter.charAt(1)) {
                case 't':
                    this.fieldDel = (byte)'\t';
                    break;

                case 'x':
                    fieldDel =
16).byteValue();
                    Integer.valueOf(delimiter.substring(2),
                    break;

                case 'u':
                    this.fieldDel =
                    Integer.valueOf(delimiter.substring(2)).byteValue();
                    break;

                default:
                    throw new RuntimeException("Unknown delimiter " +
delimiter);
            }
        } else {
            throw new RuntimeException("PigStorage delimiter must be a
single character");
        }
    }

    @Override
    public Tuple getNext() throws IOException {
        try {
            boolean notDone = in.nextKeyValue();
            if (!notDone) {
                return null;
            }
            Text value = (Text) in.getCurrentValue();
            byte[] buf = value.getBytes();
            int len = value.getLength();
            int start = 0;

            for (int i = 0; i < len; i++) {
                if (buf[i] == fieldDel) {
                    readField(buf, start, i);
                    start = i + 1;
                }
            }
            // pick up the last field

```

```

        readField(buf, start, len);

        Tuple t = mTupleFactory.newTupleNoCopy(mProtoTuple);
        mProtoTuple = null;
        return t;
    } catch (InterruptedException e) {
        int errCode = 6018;
        String errMsg = "Error while reading input";
        throw new ExecException(errMsg, errCode,
            PigException.REMOTE_ENVIRONMENT, e);
    }
}

private void readField(byte[] buf, int start, int end) {
    if (mProtoTuple == null) {
        mProtoTuple = new ArrayList<Object>();
    }

    if (start == end) {
        // NULL value
        mProtoTuple.add(null);
    } else {
        mProtoTuple.add(new DataByteArray(buf, start, end));
    }
}

@Override
public InputFormat getInputFormat() {
    return new TextInputFormat();
}

@Override
public void prepareToRead(RecordReader reader, PigSplit split) {
    in = reader;
}

@Override
public void setLocation(String location, Job job)
    throws IOException {
    FileInputFormat.setInputPaths(job, location);
}
}

```

3.2. Store Functions

[StoreFunc](#) abstract class has the main methods for storing data and for most use cases it should suffice to extend it. There is an optional interface which can be implemented to achieve extended functionality:

- [StoreMetadata](#): This interface has methods to interact with metadata systems to store schema and store statistics. This interface is truly optional and should only be

implemented if metadata needs to be stored.

The methods which need to be overridden in StoreFunc are explained below:

- `getOutputFormat()`: This method will be called by Pig to get the `OutputFormat` used by the storer. The methods in the `OutputFormat` (and underlying `RecordWriter` and `OutputCommitter`) will be called by pig in the same manner (and in the same context) as by Hadoop in a map-reduce java program. If the `OutputFormat` is a hadoop packaged one, the implementation should use the new API based one under `org.apache.hadoop.mapreduce`. If it is a custom `OutputFormat`, it should be implemented using the new API under `org.apache.hadoop.mapreduce`. The `checkOutputSpecs()` method of the `OutputFormat` will be called by pig to check the output location up-front. This method will also be called as part of the Hadoop call sequence when the job is launched. So implementations should ensure that this method can be called multiple times without inconsistent side effects.
- `setStoreLocation()`: This method is called by Pig to communicate the store location to the storer. The storer should use this method to communicate the same information to the underlying `OutputFormat`. This method is called multiple times by pig - implementations should bear in mind that this method is called multiple times and should ensure there are no inconsistent side effects due to the multiple calls.
- `prepareToWrite()`: In the new API, writing of the data is through the `OutputFormat` provided by the `StoreFunc`. In `prepareToWrite()` the `RecordWriter` associated with the `OutputFormat` provided by the `StoreFunc` is passed to the `StoreFunc`. The `RecordWriter` can then be used by the implementation in `putNext()` to write a tuple representing a record of data in a manner expected by the `RecordWriter`.
- `putNext()`: The meaning of `putNext()` has not changed and is called by Pig runtime to write the next tuple of data - in the new API, this is the method wherein the implementation will use the underlying `RecordWriter` to write the Tuple out.

The following methods have default implementations in `StoreFunc` and should be overridden only if necessary:

- `setStoreFunc!UDFContextSignature()`: This method will be called by Pig both in the front end and back end to pass a unique signature to the Storer. The signature can be used to store into the `UDFContext` any information which the Storer needs to store between various method invocations in the front end and back end. The default implementation in `StoreFunc` has an empty body. This method will be called before other methods.
- `relToAbsPathForStoreLocation()`: Pig runtime will call this method to allow the Storer to convert a relative store location to an absolute location. An implementation is provided in `StoreFunc` which handles this for `FileSystem` based locations.
- `checkSchema()`: A Store function should implement this function to check that a given schema describing the data to be written is acceptable to it. The default implementation in

StoreFunc has an empty body. This method will be called before any calls to `setStoreLocation()`.

Example Implementation

The storer implementation in the example is a storer for text data with line delimiter as `\n` and `\t` as default field delimiter (which can be overridden by passing a different field delimiter in the constructor) - this is similar to current PigStorage storer in Pig. The implementation uses an existing Hadoop supported OutputFormat - `TextOutputFormat` as the underlying OutputFormat.

```
public class SimpleTextStorer extends StoreFunc {
    protected RecordWriter writer = null;

    private byte fieldDel = '\t';
    private static final int BUFFER_SIZE = 1024;
    private static final String UTF8 = "UTF-8";
    public PigStorage() {
    }

    public PigStorage(String delimiter) {
        this();
        if (delimiter.length() == 1) {
            this.fieldDel = (byte)delimiter.charAt(0);
        } else if (delimiter.length() > 1) {
            switch (delimiter.charAt(1)) {
                case 't':
                    this.fieldDel = (byte)'\t';
                    break;

                case 'x':
                    fieldDel =
                        Integer.valueOf(delimiter.substring(2),
16).byteValue();
                    break;
                case 'u':
                    this.fieldDel =
                        Integer.valueOf(delimiter.substring(2)).byteValue();
                    break;

                default:
                    throw new RuntimeException("Unknown delimiter " +
delimiter);
            }
        } else {
            throw new RuntimeException("PigStorage delimiter must be a
single character");
        }
    }

    ByteArrayOutputStream mOut = new ByteArrayOutputStream(BUFFER_SIZE);
```

```

@Override
public void putNext(Tuple f) throws IOException {
    int sz = f.size();
    for (int i = 0; i < sz; i++) {
        Object field;
        try {
            field = f.get(i);
        } catch (ExecException ee) {
            throw ee;
        }

        putField(field);

        if (i != sz - 1) {
            mOut.write(fieldDelim);
        }
    }
    Text text = new Text(mOut.toByteArray());
    try {
        writer.write(null, text);
        mOut.reset();
    } catch (InterruptedException e) {
        throw new IOException(e);
    }
}

@SuppressWarnings("unchecked")
private void putField(Object field) throws IOException {
    //string constants for each delimiter
    String tupleBeginDelim = "(";
    String tupleEndDelim = ")";
    String bagBeginDelim = "{";
    String bagEndDelim = "}";
    String mapBeginDelim = "[";
    String mapEndDelim = "]";
    String fieldDelim = ",";
    String mapKeyValueDelim = "#";

    switch (DataType.findType(field)) {
        case DataType.NULL:
            break; // just leave it empty

        case DataType.BOOLEAN:
            mOut.write(((Boolean)field).toString().getBytes());
            break;

        case DataType.INTEGER:
            mOut.write(((Integer)field).toString().getBytes());
            break;

        case DataType.LONG:
            mOut.write(((Long)field).toString().getBytes());
            break;
    }
}

```

```

case DataType.FLOAT:
    mOut.write(((Float)field).toString().getBytes());
    break;

case DataType.DOUBLE:
    mOut.write(((Double)field).toString().getBytes());
    break;

case DataType.BYTEARRAY: {
    byte[] b = ((DataByteArray)field).get();
    mOut.write(b, 0, b.length);
    break;
}

case DataType.CHARARRAY:
    // oddly enough, writeBytes writes a string
    mOut.write(((String)field).getBytes(UTF8));
    break;

case DataType.MAP:
    boolean mapHasNext = false;
    Map<String, Object> m = (Map<String, Object>)field;
    mOut.write(mapBeginDelim.getBytes(UTF8));
    for(Map.Entry<String, Object> e: m.entrySet()) {
        if(mapHasNext) {
            mOut.write(fieldDelim.getBytes(UTF8));
        } else {
            mapHasNext = true;
        }
        putField(e.getKey());
        mOut.write(mapKeyValueDelim.getBytes(UTF8));
        putField(e.getValue());
    }
    mOut.write(mapEndDelim.getBytes(UTF8));
    break;

case DataType.TUPLE:
    boolean tupleHasNext = false;
    Tuple t = (Tuple)field;
    mOut.write(tupleBeginDelim.getBytes(UTF8));
    for(int i = 0; i < t.size(); ++i) {
        if(tupleHasNext) {
            mOut.write(fieldDelim.getBytes(UTF8));
        } else {
            tupleHasNext = true;
        }
        try {
            putField(t.get(i));
        } catch (ExecException ee) {
            throw ee;
        }
    }
    mOut.write(tupleEndDelim.getBytes(UTF8));

```

```

        break;

    case DataType.BAG:
        boolean bagHasNext = false;
        mOut.write(bagBeginDelim.getBytes(UTF8));
        Iterator<Tuple> tupleIter = ((DataBag)field).iterator();
        while(tupleIter.hasNext()) {
            if(bagHasNext) {
                mOut.write(fieldDelim.getBytes(UTF8));
            } else {
                bagHasNext = true;
            }
            putField((Object)tupleIter.next());
        }
        mOut.write(bagEndDelim.getBytes(UTF8));
        break;

    default: {
        int errCode = 2108;
        String msg = "Could not determine data type of field: " +
field;
        throw new ExecException(msg, errCode, PigException.BUG);
    }
}

@Override
public OutputFormat getOutputFormat() {
    return new TextOutputFormat<WritableComparable, Text>();
}

@Override
public void prepareToWrite(RecordWriter writer) {
    this.writer = writer;
}

@Override
public void setStoreLocation(String location, Job job) throws
IOException {
    job.getConfiguration().set("mapred.textoutputformat.separator",
    "");
    FileOutputFormat.setOutputPath(job, new Path(location));
    if (location.endsWith(".bz2")) {
        FileOutputFormat.setCompressOutput(job, true);
        FileOutputFormat.setOutputCompressorClass(job,
BZip2Codec.class);
    } else if (location.endsWith(".gz")) {
        FileOutputFormat.setCompressOutput(job, true);
        FileOutputFormat.setOutputCompressorClass(job,
GzipCodec.class);
    }
}
}

```

4. Builtin Functions and Function Repositories

Pig comes with a set of builtin functions. Two main properties differentiate builtin functions from UDFs. First, they don't need to be registered because Pig knows where they are. Second, they don't need to be qualified when used because Pig knows where to find them.

Pig also hosts a UDF repository called `piggybank` that allows users to share UDFs that they have written. The details are described in [PiggyBank](#).

5. Accumulator Interface

In Pig, problems with memory usage can occur when data, which results from a group or cogroup operation, needs to be placed in a bag and passed in its entirety to a UDF.

This problem is partially addressed by Algebraic UDFs that use the combiner and can deal with data being passed to them incrementally during different processing phases (map, combiner, and reduce.) However, there are a number of UDFs that are not Algebraic, don't use the combiner, but still don't need to be given all data at once.

The new Accumulator interface is designed to decrease memory usage by targeting such UDFs. For the functions that implement this interface, Pig guarantees that the data for the same key is passed continuously but in small increments. To work with incremental data, here is the interface a UDF needs to implement:

```
public interface Accumulator <T> {
    /**
     * Process tuples. Each DataBag may contain 0 to many tuples for current
    key
     */
    public void accumulate(Tuple b) throws IOException;
    /**
     * Called when all tuples from current key have been passed to the
    accumulator.
     * @return the value for the UDF for this key.
     */
    public T getValue();
    /**
     * Called after getValue() to prepare processing for next key.
     */
    public void cleanup();
}
```

There are several things to note here:

1. Each UDF must extend the `EvalFunc` class and implement all necessary functions there.
2. If a function is algebraic but can be used in a `FOREACH` statement with accumulator functions, it needs to implement the `Accumulator` interface in addition to the Algebraic

interface.

3. The interface is parameterized with the return type of the function.
4. The accumulate function is guaranteed to be called one or more times, passing one or more tuples in a bag, to the UDF. (Note that the tuple that is passed to the accumulator has the same content as the one passed to exec – all the parameters passed to the UDF – one of which should be a bag).
5. The getValue function is called after all the tuples for a particular key have been processed to retrieve the final value.
6. The cleanup function is called after getValue but before the next value is processed.

Here is a code snippet of the integer version of the MAX function that implements the interface:

```
public class IntMax extends EvalFunc<Integer> implements Algebraic,
Accumulator<Integer> {
    .....
    /* Accumulator interface */

    private Integer intermediateMax = null;

    @Override
    public void accumulate(Tuple b) throws IOException {
        try {
            Integer curMax = max(b);
            if (curMax == null) {
                return;
            }
            /* if bag is not null, initialize intermediateMax to negative
infinity */
            if (intermediateMax == null) {
                intermediateMax = Integer.MIN_VALUE;
            }
            intermediateMax = java.lang.Math.max(intermediateMax, curMax);
        } catch (ExecException ee) {
            throw ee;
        } catch (Exception e) {
            int errCode = 2106;
            String msg = "Error while computing max in " +
this.getClass().getSimpleName();
            throw new ExecException(msg, errCode, PigException.BUG, e);
        }
    }

    @Override
    public void cleanup() {
        intermediateMax = null;
    }

    @Override
    public Integer getValue() {
        return intermediateMax;
    }
}
```

```
}
}
```

6. Advanced Topics

6.1. UDF Interfaces

A UDF can be invoked multiple ways. The simplest UDF can just extend `EvalFunc`, which requires only the `exec` function to be implemented (see [How to Write a Simple Eval Function](#)). Every eval UDF must implement this. Additionally, if a function is algebraic, it can implement `Algebraic` interface to significantly improve query performance in the cases when combiner can be used (see [Aggregate Functions](#)). Finally, a function that can process tuples in an incremental fashion can also implement the `Accumulator` interface to improve query memory consumption (see [Accumulator Interface](#)).

The exact method by which UDF is invoked is selected by the optimizer based on the UDF type and the query. Note that only a single interface is used at any given time. The optimizer tries to find the most efficient way to execute the function. If a combiner is used and the function implements the `Algebraic` interface then this interface will be used to invoke the function. If the combiner is not invoked but the accumulator can be used and the function implements `Accumulator` interface then that interface is used. If neither of the conditions is satisfied then the `exec` function is used to invoke the UDF.

6.2. Function Instantiation

One problem that users run into is when they make assumption about how many times a constructor for their UDF is called. For instance, they might be creating side files in the store function and doing it in the constructor seems like a good idea. The problem with this approach is that in most cases Pig instantiates functions on the client side to, for instance, examine the schema of the data.

Users should not make assumptions about how many times a function is instantiated; instead, they should make their code resilient to multiple instantiations. For instance, they could check if the files exist before creating them.

6.3. Schemas

One request from users is to have the ability to examine the input schema of the data before processing the data. For example, they would like to know how to convert an input tuple to a map such that the keys in the map are the names of the input columns. The current answer is that there is no way to do this. This is something we would like to support in the future.

6.4. Passing Configurations to UDFs

The singleton `UDFContext` class provides two features to UDF writers. First, on the backend, it allows UDFs to get access to the `JobConf` object, by calling `getJobConf`. This is only available on the backend (at run time) as the `JobConf` has not yet been constructed on the front end (during planning time).

Second, it allows UDFs to pass configuration information between instantiations of the UDF on the front and backends. UDFs can store information in a configuration object when they are constructed on the front end, or during other front end calls such as `describeSchema`. They can then read that information on the backend when `exec` (for `EvalFunc`) or `getNext` (for `LoadFunc`) is called. Note that information will not be passed between instantiations of the function on the backend. The communication channel only works from front end to back end.

To store information, the UDF calls `getUDFProperties`. This returns a `Properties` object which the UDF can record the information in or read the information from. To avoid name space conflicts UDFs are required to provide a signature when obtaining a `Properties` object. This can be done in two ways. The UDF can provide its `Class` object (via `this.getClass()`). In this case, every instantiation of the UDF will be given the same `Properties` object. The UDF can also provide its `Class` plus an array of `Strings`. The UDF can pass its constructor arguments, or some other identifying strings. This allows each instantiation of the UDF to have a different properties object thus avoiding name space collisions between instantiations of the UDF.

6.5. Monitoring long-running UDFs

Sometimes one may discover that a UDF that executes very quickly in the vast majority of cases turns out to run exceedingly slowly on occasion. This can happen, for example, if a UDF uses complex regular expressions to parse free-form strings, or if a UDF uses some external service to communicate with. As of version 0.8, Pig provides a facility for monitoring the length of time a UDF is executing for every invocation, and terminating its execution if it runs too long. This facility can be turned on using a simple Java annotation:

```
import org.apache.pig.builtin.MonitoredUDF;

@MonitoredUDF
public class MyUDF extends EvalFunc<Integer> {
    /* implementation goes here */
}
```

Simply annotating your UDF in this way will cause Pig to terminate the UDF's `exec()` method if it runs for more than 10 seconds, and return the default value of null. The duration

of the timeout and the default value can be specified in the annotation, if desired:

```
import org.apache.pig.builtin.MonitoredUDF;

@MonitoredUDF(timeUnit = TimeUnit.MILLISECONDS, duration = 100,
intDefault = 10)
public class MyUDF extends EvalFunc<Integer> {
    /* implementation goes here */
}
```

intDefault, longDefault, doubleDefault, floatDefault, and stringDefault can be specified in the annotation; the correct default will be chosen based on the return type of the UDF. Custom defaults for tuples and bags are not supported at this time.

If desired, custom logic can also be implemented for error handling by creating a subclass of MonitoredUDFExecutor.ErrorCallback, and overriding its handleError and/or handleTimeout methods. Both of those methods are static, and are passed in the instance of the EvalFunc that produced an exception, as well as an exception, so you may use any state you have in the UDF to process the errors as desired. The default behavior is to increment Hadoop counters every time an error is encountered. Once you have an implementation of the ErrorCallback that performs your custom logic, you can provide it in the annotation:

```
import org.apache.pig.builtin.MonitoredUDF;

@MonitoredUDF(errorCallback=MySpecialErrorCallback.class)
public class MyUDF extends EvalFunc<Integer> {
    /* implementation goes here */
}
```

Currently the MonitoredUDF annotation works with regular and Algebraic UDFs, but has no effect on UDFs that run in the Accumulator mode.

7. Python UDFs

7.1. Syntax

7.1.1. Registering Scripts

You can register a Python script as shown here. This example uses org.apache.pig.scripting.jython.JythonScriptEngine to interpret the python script. You can develop and use custom script engines to support multiple programming languages and ways to interpret them. Currently, Pig identifies jython as a keyword and ships the required scriptengine (jython) to interpret it.

```
Register 'test.py' using jython as myfuncs;
```

The following syntax is also supported, where myfuncs is the namespace created for all the functions inside test.py.

```
register 'test.py' using org.apache.pig.scripting.jython.JythonScriptEngine
as myfuncs;
```

A typical test.py looks like this:

```
@outputSchema("word:chararray")
def helloworld():
    return 'Hello, World'

@outputSchema("word:chararray,num:long")
def complex(word):
    return str(word),len(word)

@outputSchemaFunction("squareSchema")
def square(num):
    return ((num)*(num))

@schemaFunction("squareSchema")
def squareSchema(input):
    return input

# No decorator - bytearray
def concat(str):
    return str+str
```

The register statement above registers the python functions defined in test.py in Pig's runtime within the defined namespace (myfuncs here). They can then be referred later on in the pig script as myfuncs.helloworld(), myfuncs.complex(), and myfuncs.square(). An example usage is:

```
b = foreach a generate myfuncs.helloworld(), myfuncs.square(3);
```

7.1.2. Decorators and Schemas

To annotate a python script so that Pig can identify return types, use python decorators to define output schema for the script UDF.

- `outputSchema` - Defines schema for a script udf in a format that Pig understands and is able to parse.
- `outputFunctionSchema` - Defines a script delegate function that defines schema for this function depending upon the input type. This is needed for functions that can accept generic types and perform generic operations on these types. A simple example is square which can accept multiple types. SchemaFunction for this type is a simple identity function (same schema as input).
- `schemaFunction` - Defines delegate function and is not registered to Pig.

When no decorator is specified, Pig assumes the output datatype as bytearray and converts the output generated by script function to bytearray. This is consistent with Pig's behavior in case of Java UDFs.

Sample Schema String - `y:{t:(word:chararray,num:long)}`, variable names inside a schema string are not used anywhere, they just make the syntax identifiable to the parser.

7.2. Inline Scripts

Currently, Pig does not support UDFs using inline scripts.

7.3. Sample Script UDFs

Simple tasks like string manipulation, mathematical computations, and reorganizing data types can be easily done using python scripts without having to develop long and complex UDFs in Java. The overall overhead of using scripting language is much less and development cost is almost negligible. The following UDFs, developed in python, can be used with Pig.

```
mySampleLib.py
-----
#!/usr/bin/python

#####
# Math functions #
#####
#Square - Square of a number of any data type
@outputSchemaFunction("squareSchema")
def square(num):
    return ((num)*(num))
@schemaFunction("squareSchema")
def squareSchema(input):
    return input

#Percent- Percentage
@outputSchema("percent:double")
def percent(num, total):
    return num * 100 / total

#####
# String Functions #
#####
#commaFormat- format a number with commas, 12345-> 12,345
@outputSchema("numformat:chararray")
def commaFormat(num):
    return '{:,}'.format(num)

#concatMultiple- concat multiple words
```

```
@outputSchema("onestring:chararray")
def concatMult4(word1, word2, word3, word4):
    return word1+word2+word3+word4

#####
# Data Type Functions #
#####
#collectBag- collect elements of a bag into other bag
#This is useful UDF after group operation
@outputSchema("y:bag{t:tuple(len:int,word:chararray)}")
def collectBag(bag):
    outBag = []
    for word in bag:
        tup=(len(bag), word[1])
        outBag.append(tup)
    return outBag

# Few comments-
# pig mandates that a bag should be a bag of tuples, python UDFs should
follow this pattern.
# tuple in python are immutable, appending to a tuple is not possible.
```
